

The dual effect of Antarctic krill on phytoplankton blooms - grazing and nutrient supply

Katrin Schmidt, University of Plymouth (katrin.schmidt@plymouth.ac.uk)
 Angus Atkinson, Plymouth Marine Laboratory
 and many other Piccoliños

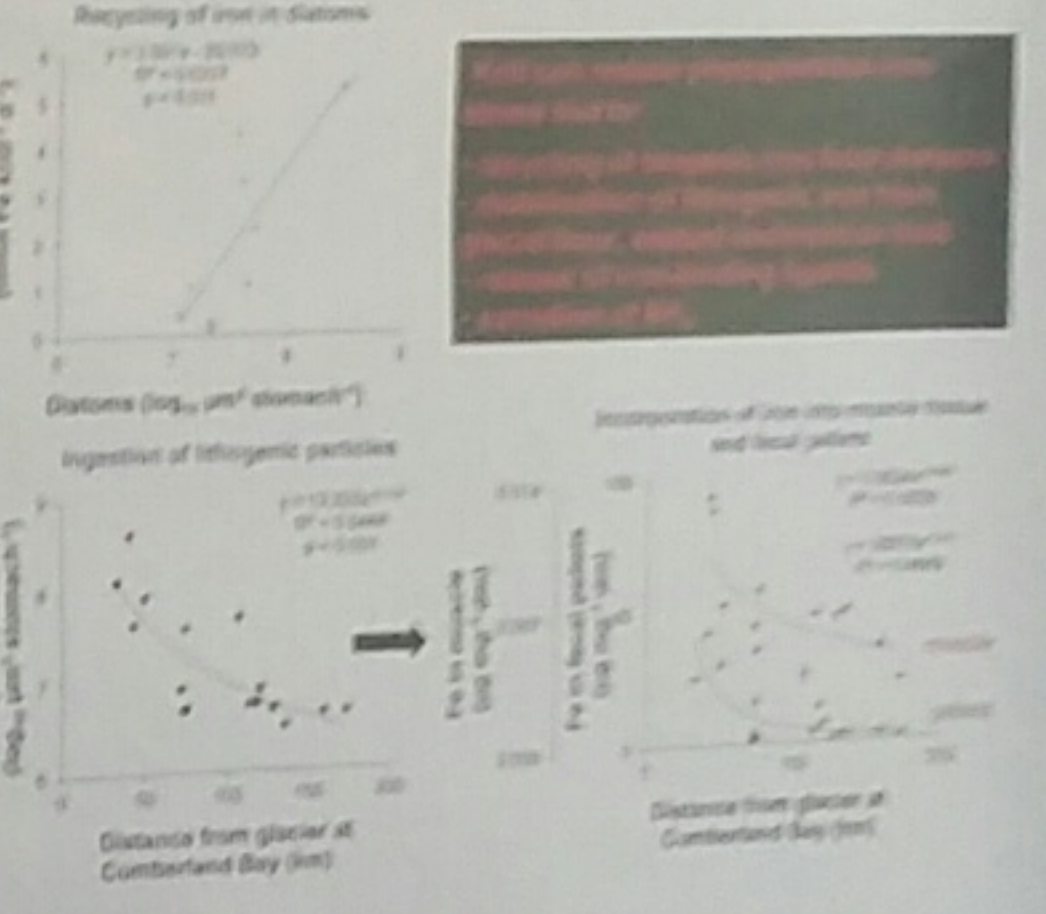

Why are krill likely to be important in SO carbon- and nutrient cycles?

(1) The SO is a 'sea of giants'

In UK shelf seas, the spring-summer primary producer community is often dominated by nanoplankton (2-20 µm), while macroplankton (>20 µm) are rare (14% of total Chl a). In the SO, the micro-size fraction is much more prevalent, contributing 46% of total Chl a. These large diatoms are efficiently grazed by giant zooplankton - krill, salps and large copepods. The biomass of Antarctic krill is estimated to be similar to the global biomass of cattle (180-500 million tonnes). Key to these high krill abundances are their relatively low mortality rates and longevity, and their ability to migrate within systems to search for feeding grounds. With the reduction of sea ice and other climate-related changes in the Atlantic sector of the SO, krill abundances are in decline.

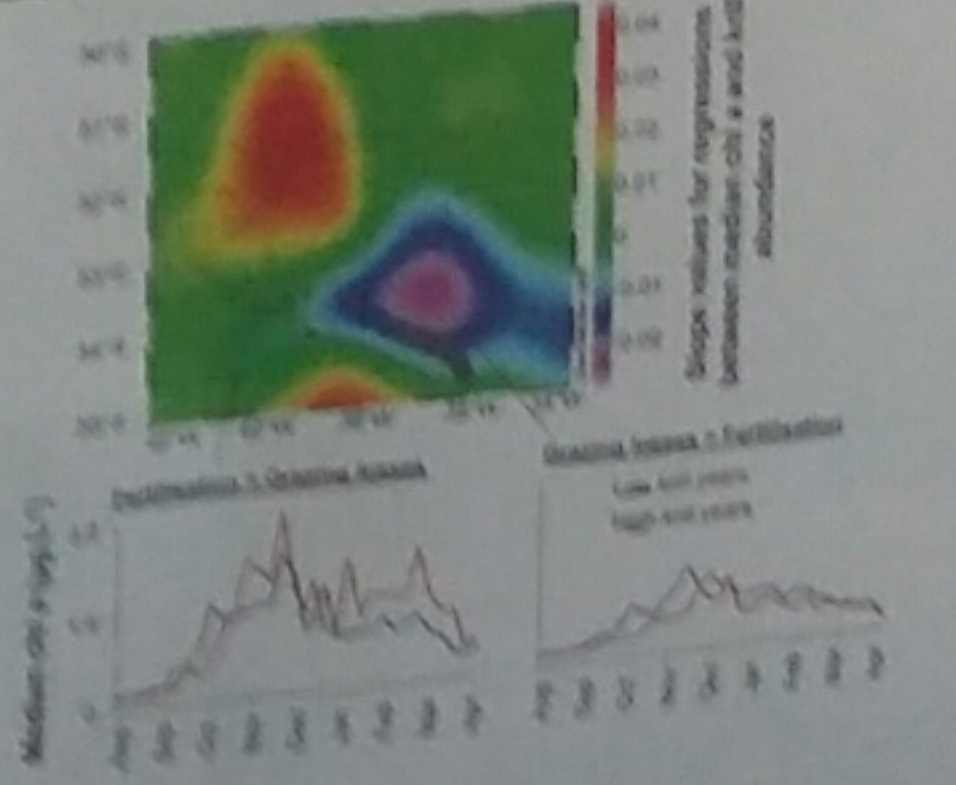

(2) Krill can recycle biogenic iron and mobilise lithogenic iron

Krill can recycle biogenic iron and mobilise lithogenic iron. Recycling of iron in diatoms. Diatoms (µg µm³ seawater). Lithogenic particles (µg µm³ seawater). Fe in krill excretion (µg µm³ d⁻¹). Distance from glacier at Cumberland Bay (km).

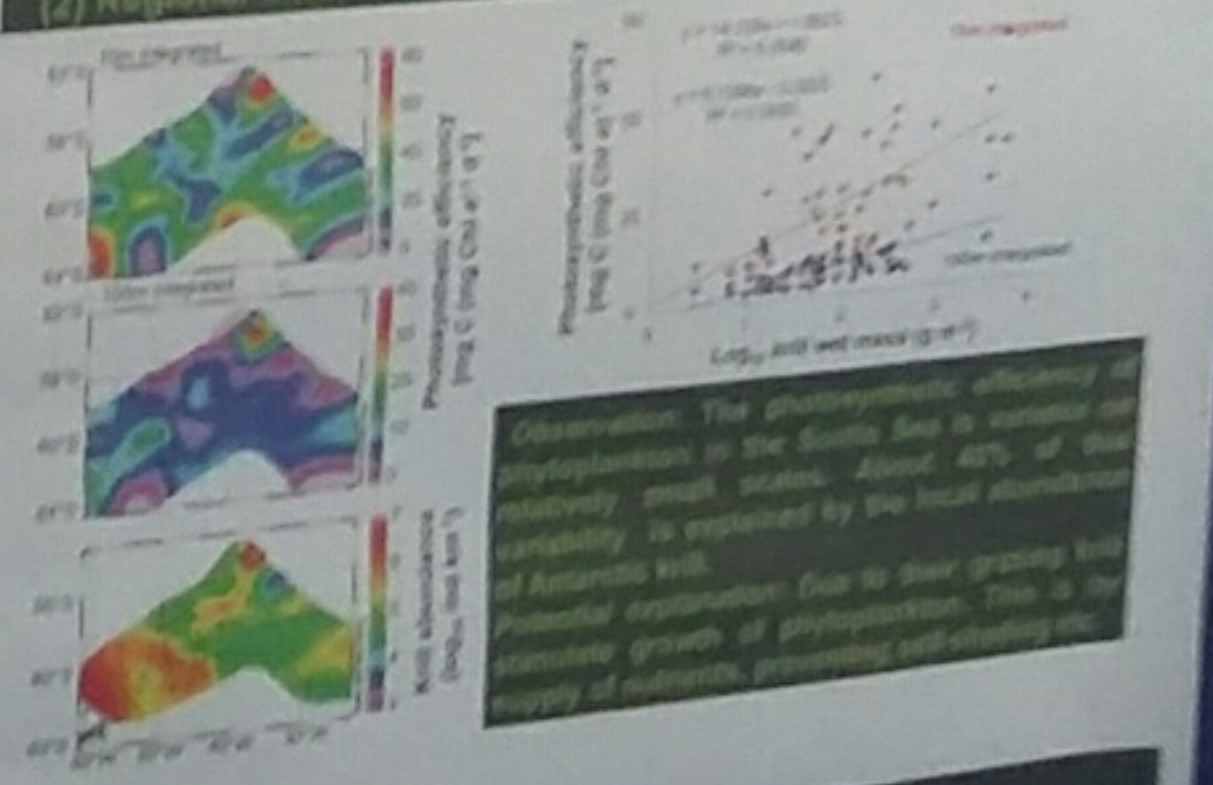

In situ indications of krill stimulating phytoplankton growth in the SO

(1) Interannual variability in the phytoplankton bloom downstream of S. Georgia

Observation: Years with high krill abundances on the South Georgia shelf coincide with lower chl a concentrations on the shelf (blue-purple area), but higher chl a concentrations downstream the island (yellow-red area). Potential explanation: On the shelf, grazing losses by krill outweigh potential benefits of losses by krill excretion and phytoplankton fertilisation, but downstream fertilising effects outweigh grazing losses. Potential processes involved: Krill: recycling and mobilisation of iron & other trace elements, supply of ligands, DOM, NH, etc. Microbes, other zooplankton: recycling of iron in krill fecal pellets and 'slippy feeding' products. Krill predators: Release of iron from krill tissue. Pennate diatoms: luxury iron uptake on the shelf and transport to downstream bloom area with the current flow (black lines - drifter trajectories).

(2) Regional differences in photosynthetic efficiency of phytoplankton

Observation: The photosynthetic efficiency of phytoplankton in the Scotia Sea is variable at relatively small scales. About 42% of this variability is explained by the local abundance of Antarctic krill. Potential explanation: due to their grazing and potential excretion of phytoplankton. This is by supply of nutrients, providing self-shading etc.

Planned krill work during PICCOLO addressing Hypothesis 2 of WP3 (more details on WP3 on separate poster)

- (1) Shipboard rate measurements of dissolved- and particulate iron release by key zooplankton grazers (Antarctic krill, ice krill, large copepods) along a potential iron-gradient from the Weddell Gyre to Weddell Sea shelf areas and the seasonally retreating ice edge (in cooperation with PICCOLO WP2)
- (2) Estimation of nutrient stoichiometry (C:N:Fe) in zooplankton body tissue, fecal pellets and dissolved excretates (in cooperation with PICCOLO WP2)
- (3) Relating photosynthetic efficiency and photophysiology of local phytoplankton communities to in situ NH₄⁺ concentrations and abundance of Antarctic krill and other grazers (based on acoustic estimates)
- (4) Testing the hypothesis that high iron concentrations in krill in the Weddell Sea are related to their grazing on the sea ice community (using the Antarctic sea ice proxy IPSC₂)
